Abstract

We introduce a new method for decoding short and moderate length linear block codes with dense parity-check matrix representations of cyclic form, termed multiple-bases belief-propagation (MBBP). The proposed iterative scheme makes use of the fact that a code has many structurally diverse parity-check matrices, capable of detecting different error patterns. We show that this inherent code property leads to decoding algorithms with significantly better performance when compared to standard BP decoding. Furthermore, we describe how to choose sets of parity-check matrices of cyclic form amenable for multiple-bases decoding, based on analytical studies performed for the binary erasure channel. For several cyclic and extended cyclic codes, the MBBP decoding performance can be shown to closely follow that of maximum-likelihood decoders.

Index Terms: Algebraic Codes, Belief Propagation, Multiple-Bases Belief-Propagation Decoding, Stopping Sets.

1 Introduction

Classical algebraic codes of short block length have large minimum distance and efficient soft-decision decoding algorithms [1, 2, 3]. Consequently, these codes represent a good choice for low-delay applications where high transmission reliability is required. Algebraic codes are also frequently used as components of product codes and parts of concatenated coding schemes. In modern storage and communication systems, low-density parity-check (LDPC) codes are most often used as the inner coding scheme. For this reason it is desirable to implement a soft-input soft-output decoder for algebraic codes as a belief-propagation (BP) algorithm. This is a reasonable choice as the decoder can handle both types of codes. Since algebraic block codes have dense parity-check matrices with a large number of short cycles [4, 5], BP decoders offer poor error-correcting performance for such codes.

*Parts of the results were presented at the IEEE International Symposium on Information Theory (ISIT), Nice, France, 2007. The work was supported in part by the NSF grant CCF 0644427 awarded to Olgica Milenkovic.

The use of redundant parity-check matrices for iterative decoding schemes when signaling over the binary erasure channel (BEC) has been excessively studied. Several authors proposed using a high number of redundant checks [6, 7, 8, 9] to improve the decoding performance. This type of decoding has also drawn the attention of researchers who studied this concept in the context of the AWGN channel. Other authors proposed *adaptive BP algorithms* [10, 11], which iteratively optimize the matrix representation during the decoding process. Such schemes have large implementation complexity due to the required matrix reduction after each iteration. The *random redundant decoding* (RRD) [4] algorithm does not require this type of processing and obtains very promising results. This is accomplished by serially altering the applied matrix representation within the decoding process. Another closely related approach was described in [12], where a simple simulation-based study using randomly chosen parity-check matrices of the [24, 12, 8] extended Golay code was performed. This approach offers poor performance when compared both to the performance of the RRD algorithm and the algorithms described in this work.

The approach followed in this paper draws upon the prior work of the authors on BEC decoding [13] and introduces a novel decoding method that operates in parallel and iterative fashion on a collection of parity-check matrices. Using this set of decoder representations, the algorithm performs joint output processing in order to estimate the transmitted codeword. This output processing can occur at various stages of decoding and it may have various degrees of complexity. We distinguish between techniques where the BP algorithms run separately and compare them to schemes where the decoders are allowed to exchange information. In the latter case, we investigate processing of the form of *metric and complexity selection*, *averaging of probabilities* [14], *information combining* [15], as well as certain reliability-based schemes.

As the different representations of the parity-check matrix form bases of the dual code, we refer to the proposed approaches as *Multiple-Bases Belief-Propagation* (MBBP) decoding. For the purpose of MBBP decoding, one needs to identify classes of parity-check matrices that *jointly* offer good decoding performance. In order to accomplish this task, we propose using parity-check matrix design techniques originally developed for the BEC but subsequently used for signaling over the AWGN channel. This approach leads to good performance results, as observed both by the authors and other researchers [16]. Moreover, this method relies on the fact that the performance of a parity-check matrix for the BEC is completely characterized by combinatorial entities termed stopping sets [17]; and, that pseudocodewords for linear programming decoders of several classes of channels represent stopping sets for any channel in the Tanner graph [18, 19]. Although we focus our attention on parity-check matrix construction techniques for cyclic codes, the described concepts can be generalized for other classes of codes as well.

The main differences between the existing RRD algorithm and the proposed MBBP scheme are that RRD operates in a *serial* fashion in terms of periodically permuting the received word, while MBBP works in a parallel manner. Further, the RRD algorithm uses message scaling processing between iterations that tends to increase the overall complexity of the scheme. Contrary, the MBBP algorithm deploys the standard update rules defined by message passing decoding within its parallel cores. Finally, the RRD algorithm uses a greedy search over the Tanner graphs to find a representation which offers

good performance as well as random shuffling techniques of the variable nodes. The MBBP algorithm relies on specially designed parity-check matrix families for a given code.

The paper is organized as follows. Section 2 introduces relevant definitions and terminology, while Section 3 contains a description of the bases selection process. Section 4 presents a set of different variations of MBBP decoding algorithms. Simulation results are presented in Section 5.

2 Definitions and Terminology

We start by introducing the terminology related to stopping sets and the BEC. We also provide the terminology needed for describing the MBBP decoding approach.

Definition 2.1. Let $\mathbf{A}$ be an $m \times n$ matrix, and let the columns of $\mathbf{A}$ be indexed by the set of integers $\mathcal{J} = \{0, \dots, n-1\}$. For a set $\mathcal{I} \subseteq \mathcal{J}$, we define the restriction of $\mathbf{A}$ to $\mathcal{I}$ as the $m \times |\mathcal{I}|$ array of elements composed of the columns of $\mathbf{H}$ indexed by $\mathcal{I}$.

When transmitting over the BEC, stopping sets completely determine the failure modes of iterative decoders. For completeness we define these sets below [17].

Definition 2.2. For a given parity-check matrix $\mathbf{H}$ of an $[n, k, d]$ binary linear code $\mathcal{C}$, a stopping set $\mathcal{S}(\mathbf{H})$ of size σ is a set $\mathcal{I}$ of σ positions in the codeword for which the restriction of $\mathbf{H}$ to $\mathcal{I}$ does not contain rows of Hamming weight one.

Clearly, a codeword is a stopping set and consequently the size of the smallest stopping set of any given parity-check matrix cannot exceed d .

In order to compare different parity-check matrix representations with respect to their decoding performance, we restrict our attention to a simple evaluation criteria: the number of stopping sets of size less than or equal to σ , for some predefined value $1 \leq \sigma \leq d$. Given a parity-check matrix $\mathbf{H}$, the number of its stopping sets of size σ will henceforth be denoted by $|\mathcal{S}_\sigma(\mathbf{H})|$. Although stopping sets are known to completely characterize the performance of iterative decoders *only* for the BEC, they also represent a partial performance indicator for transmission over the AWGN channel. This is due to the intimate connection between stopping sets and pseudocodewords [18, 20].

As we focus our attention on codes with parity-check matrices of cyclic form, a code category that includes cyclic codes, we also provide the following definitions.

Definition 2.3. Let $\mathcal{C}$ be a binary, linear code and $\mathcal{C}^\perp$ its dual. A parity-check matrix of $\mathcal{C}$ is said to be of cyclic form if it consists of $n - k \leq m \leq n$ consecutive cyclic shifts of one chosen codeword of $\mathcal{C}^\perp$. In this context, the qualifier “consecutive” implies that the $(i+1)$ -th row of the parity-check matrix, $1 \leq i \leq m-1$, is the cyclic right shift of the i -th row by one position.

A code $\mathcal{C}$ is called cyclic if any cyclic shift of a codeword $\mathbf{c} \in \mathcal{C}$ is also a codeword, and it necessarily has at least one parity-check matrix of cyclic form.

For a code with at least one parity-check matrix of cyclic form, we introduce the notion of a partition of the set of codewords of $\mathcal{C}^\perp$ and the notion of a cyclic orbit generator (*cog*).

Definition 2.4. *Let $\mathcal{C}$ be a binary, linear, cyclic code. Partition the set of codewords of $\mathcal{C}^\perp$ into disjoint orbits (subsets) consisting of cyclic shifts of one codeword. Let one designated codeword in the orbit be the representative of the subset. This codeword is referred to as the cyclic orbit generator (*cog*).*

Throughout the paper we focus our attention on cogs of minimum Hamming weight. Little technical modifications are required in the above definition to encompass parity-check matrices that are of cyclic form when restricted to a proper subset of columns, e.g. extended cyclic codes.

Let $\mathcal{G}$ be the set of cyclic orbit generators with Hamming weight equal to the minimum distance of the dual code, $d^\perp$. A cyclic orbit generator $\text{cog}_\ell \in \mathcal{G}$, $\ell = 1, \dots, |\mathcal{G}|$, is used to construct a parity-check matrix $\mathbf{H}_\ell$, $\ell = 1, \dots, |\mathcal{G}|$, of size $m \times n$, $n - k \leq m \leq n$, such that the row-rank of the matrix is $n - k^1$. This matrix consists of m consecutive right shifts of cog_ℓ . To avoid identical rows in $\mathbf{H}_\ell$ even if $m = n$ holds, only cogs with a period of n , i.e. cogs with a cyclic orbit that consists of n distinct shifts, are considered for the construction process.

Note that a redundant parity-check matrix of cyclic form can have at most n distinct rows². The larger the value of m , the larger the hardware implementation complexity of the BP decoder. Nevertheless, based on extensive computer simulations, it was observed that for decoding of algebraic codes signaled over the AWGN channel the best decoding performance is achieved for $m = n$. This finding holds for both the *bit error rate* (BER) and *frame error rate* (FER). The reason supporting this observation is intuitively clear. Consider a parity-check matrix of cyclic form for which $m = n - k$, as shown in (1) for $m = 3, n = 7$. Here, the symbol x serves as placeholder for the bits of the generating cog of the matrix.

$$\left(\begin{array}{cc|ccc|cc} 1 & x & x & x & 1 & 0 & 0 \\ 0 & 1 & x & x & x & 1 & 0 \\ 0 & 0 & 1 & x & x & x & 1 \end{array} \right) \quad (1)$$

As can be seen from (1), not all of the seven bits participate in the same number of parity-check equations - the column degrees of the parity-check matrix vary with the column. There exist at least two bits (including the first and last) that participate in only one parity-check, and therefore have very low probability of being correctly decoded. Depending on the particular choice of the cog, the set of symbols at the beginning and at the end of the codeword is strongly restricted with respect to the maximum number of parity-checks it can participate in. This problem can be solved by setting $m = n$: such a row-redundancy allows for achieving equal error protection for all code symbols [22]. Therefore, square parity-check matrices will be used throughout the remainder of this paper.

We conclude this section by introducing the notion of a cog *family* of a set of parity-check matrices.

¹Here, and throughout the paper, we only consider cogs that generate parity-check matrices with row-rank $n - k$. As a consequence, we use the word *bases* to describe the underlying matrices, although the considered structures are actually *frames*. Frames are over-complete systems in which every element of a vector space can be represented in a not necessarily unique manner [21].

²Cyclic matrices with $m = n$ rows are also referred to as circulant matrices.

Definition 2.5. Let $\mathcal{F}_1, \mathcal{F}_2, \dots, \mathcal{F}_F$ be a partition of the set of indices $\{1, \dots, |\mathcal{G}|\}$, i.e.

$$\mathcal{F}_1 \cup \mathcal{F}_2 \cup \dots \cup \mathcal{F}_F = \{1, \dots, |\mathcal{G}|\} \text{ and } \mathcal{F}_f \cap \mathcal{F}_{f'} = \emptyset, \forall f \neq f',$$

so that the “stopping set performance” of $\mathbf{H}_\ell$ is fixed within each family $\mathcal{F}_f$, for all $\ell \in \mathcal{F}_f$, and for all $f \in \{1, \dots, F\}$, and this claim is true for all families in the partition. The “stopping set performance” of a parity-check matrix, defined for both the BEC and AWGN channel, is the number of stopping sets of size up to and including d . We refer to the set $\{\text{cog}_\ell\}$, $\ell \in \mathcal{F}_f$, as the f -th cog family.

3 Bases Selection for MBBP decoding

Recall that a linear $[n, k, d]$ code $\mathcal{C}$ is uniquely defined by a parity-check matrix $\mathbf{H}$ of rank $n - k$ or a generator matrix $\mathbf{G}$ of rank k . There usually exists a large number of generator and parity-check matrices for the same code. For BP decoding over AWGN channels, one usually seeks a sparse parity-check matrix $\mathbf{H}$. The performance of the algorithm strongly depends on some additional structural properties of $\mathbf{H}$, such as the number and weight of pseudocodewords.

Adding redundant rows to parity-check matrices improves the performance of iterative decoding for the BEC, but usually has detrimental effects on BP decoders correcting data signaled over the AWGN channel. This can be attributed to the increase of the number of short cycles and the density of the matrix. But, as was shown by the authors in [23], adding judiciously chosen redundant rows may increase the minimum weight of pseudocodewords (and trapping sets) of the given parity-check matrix.

In order to exploit the benefits offered by redundant parity-check matrices with respect to pseudocodeword performance, while controlling the negative effects on the cycle lengths, the following approach can be used. Rather than decoding a received word in terms of only one parity-check matrix, one can use a collection of parity-check matrices, each with small row-redundancy, in parallel. The results of the decoders operating on different parity-check matrices can then be appropriately combined. This is the main idea behind MBBP decoding, and for this purpose, we propose to develop good heuristic techniques for identifying parity-check matrices which offer both good individual and joint decoding performance.

For cyclic algebraic codes, we proved in a companion paper [13] that parity-check matrices that consist of cyclic shifts of carefully chosen cogs offer excellent stopping set properties [24]. In what follows, we focus on identifying families of cogs that obtain very good decoding performance for the AWGN channel. As already pointed out, the iterative decoding performance of a fixed parity-check matrix used over the AWGN channel is, to a certain extent, strongly correlated with its BEC performance, so that we use the total number of stopping sets of size up to d as our cog family optimization criteria.

Since cogs from the same family define parity-check matrices of cyclic form with identical properties for the BEC and comparable properties for the AWGN channel, it is desirable to identify the family with the best performance and then exclusively use cogs from this family to build matrices for MBBP decoding. Identifying all families along with its members by counting stopping sets in the corresponding

matrices is computationally expensive [25]. Also, storing all cogs used for decoding can be prohibitively costly, especially for long codes and MBBP decoders with many bases. In order to avoid these problems, we propose to use a cog *mapping technique* that relies on the notion of the *automorphism group* of a code.

Definition 3.1. [26, Ch. 8] *The permutations which send $\mathcal{C}$ into itself, i.e. codewords go into (possibly different) codewords, form the automorphism group of the code $\mathcal{C}$, denoted by $\text{Aut}(\mathcal{C})$. If $\mathcal{C}$ is a linear code and $\mathcal{C}^\perp$ is its dual code, then $\text{Aut}(\mathcal{C}) = \text{Aut}(\mathcal{C}^\perp)$.*

It is straightforward to prove that there exists a set of permutations $\mathcal{P}$ in the automorphism group of a cyclic code which map one cog into another cog from the same family. Fixing one cog, and then applying a subset of permutations from $\mathcal{P}$ to it, represents a convenient way for generating redundant parity-check matrices with identical densities and comparable performance under MBBP decoding.

We provide next a partial characterization of the set $\mathcal{P}$ for cyclic codes. More precisely, we describe how to find a large set of permutations $\mathcal{P}$ for which $|\mathcal{S}_\sigma(\mathbf{H}_a)| = |\mathcal{S}_\sigma(\mathbf{H}_b)|$, for $\sigma \leq n$, where the generating cogs of $\mathbf{H}_a$ and $\mathbf{H}_b$ satisfy $\text{cog}_b = \kappa(\text{cog}_a)$, and where $\kappa(\cdot) \in \mathcal{P}$. Here, $\kappa(\text{cog}_a)$ is used to denote the action of the permutation κ on the vector cog_a . Note that the same framework can be used when only stopping sets up to a size smaller than or equal to d are considered.

It is well known that the automorphism group of a cyclic code contains two classes of permutations [26]:

P_1 : The class of cyclic permutations $\alpha^0, \alpha^1, \dots, \alpha^{n-1}$, where

$$\begin{aligned} \alpha : i &\rightarrow (i + 1) \bmod n, \quad i = 0, \dots, n - 1, \\ \alpha(\mathbf{c}) &= (c_{n-1}, c_0, c_1, \dots, c_{n-2}). \end{aligned}$$

P_2 : The class of permutations $\beta^0, \beta^1, \dots, \beta^{h-1}$, where

$$\begin{aligned} \beta : i &\rightarrow (2 \cdot i) \bmod n, \quad i = 0, \dots, n - 1, \\ \beta(\mathbf{c}) &= (c_0 c_{(n+1)/2} c_1 \dots c_{(n-1)/2}), \end{aligned} \tag{2}$$

and where h denotes the cardinality of the cyclotomic coset of the n -th roots of unity that contains one. Above, all subscripts are taken modulo n . For extended cyclic codes, the described permutations are only to be applied to the cyclic part of the codeword.

We find the following definition useful for our subsequent derivations.

Definition 3.2. *Let κ be a permutation operating on a vector $\mathbf{v}$, resulting in a vector $\mathbf{t} = \kappa(\mathbf{v})$. We define the κ -permutation of an $m \times n$ matrix $\mathbf{V}$ as a matrix obtained by permuting each row of $\mathbf{V}$*

according to κ . In this setting, $\mathbf{T} = \kappa(\mathbf{V})$ is used to denote $\mathbf{T}(\mu, :) = \kappa(\mathbf{V}(\mu, :))$, $\mu = 1, \dots, m$, where $\mathbf{X}(\mu, :)$ represents the μ -th row of the matrix $\mathbf{X}$.

The following straightforward results provide a partial characterization of the set of permutations $\mathcal{P}$ of cyclic codes. All proofs rely on the fact that $\alpha^j \theta = \theta \alpha^{j'}$, for any integer j and some integer j' , and for $\theta \in \mathcal{A}(n)$, the affine group of order n .

Lemma 3.3. *A necessary and sufficient condition for*

$$\begin{aligned} \theta(\alpha^j(\text{cog}_a)) &= \alpha^{j'}(\theta(\text{cog}_a)), \\ &\text{for all } j \in \{0, \dots, n-1\}, \\ &\text{and some } j' \in \{0, \dots, n-1\}, \end{aligned}$$

to hold is that $\theta(\cdot)$ is an affine permutation, defined as

$$\begin{aligned} \theta : \quad i &\rightarrow q \cdot i + \omega \bmod n, \\ &\text{for some } q \in \{0, \dots, n-1\}, \omega \in \{0, \dots, n-1\}, \text{ and } i = 0, \dots, n-1, \end{aligned}$$

such that $\gcd(q, n) = 1$. Here, $\gcd(q, n)$ is used to denote the greatest common divisor of q and n .

Proof. The claim of Lemma 3.3 can be rewritten as

$$\begin{aligned} \theta(i+j) &= \theta(i) + j' \bmod n \\ j &\in \{0, \dots, n-1\}, j' \in \{0, \dots, n-1\}, i = 0, \dots, n-1, \end{aligned}$$

where $\theta(i)$ denotes the action of the permutation θ on the coordinate i .

The former equality is true if and only if $\theta(i)$ is a linear function of the form $q \cdot i + \omega$ for which $\gcd(q, n) = 1$. $\square$

The lemma asserts that cyclic permutations commute (up to a cyclic shift) with all affine permutations in a symmetric group.

Example 3.1. Consider $n = 5$, $j = 1$, and $\theta : i \rightarrow i + 2 \bmod n$, $i = 0, \dots, n-1$. Then, $\theta(\alpha(10100)) = \alpha(\theta(10100)) = 10010$ holds. In this special case, both j and j' are equal to one.

Claim 3.4. If $\text{cog}_b = \alpha^j(\text{cog}_a)$, for some $j \in \{0, \dots, n-1\}$, then

$$|\mathcal{S}_\sigma(\mathbf{H}_a)| = |\mathcal{S}_\sigma(\mathbf{H}_b)|, \text{ for all } \sigma \leq n.$$

Proof. Applying α^j to cog_a cyclically permutes the rows of $\mathbf{H}_a$. This cyclic permutation preserves all stopping sets, which proves the claimed result. $\square$

Claim 3.5. *If $\text{cog}_c = \beta^j(\text{cog}_a)$, for some $j \in \{0, \dots, h-1\}$, then*

$$|\mathcal{S}_\sigma(\mathbf{H}_a)| = |\mathcal{S}_\sigma(\mathbf{H}_c)|, \text{ for all } \sigma \leq n.$$

Proof. It is straightforward to see that

$$\begin{aligned} \mathbf{H}_c(\mu, :) &= \alpha^{\mu-1}(\mathbf{H}_c(1, :)) = \alpha^{\mu-1}(\beta^j(\mathbf{H}_a(1, :))) \\ &= \beta^j(\alpha^{\mu'-1}(\mathbf{H}_a(1, :))), \end{aligned}$$

since β^j is an affine permutation with $q = 2$ and $\omega = 0$. As a result, $\mathbf{H}_c$ can be transformed into $\mathbf{H}_a$ through row- and column-permutations. $\square$

We conclude that $\mathcal{A}(n) \cap \text{Aut}(\mathcal{C}) \subseteq \mathcal{P}$: in other words, applying affine transforms from the automorphism group of the code to one chosen cog in the family produces cogs that generate parity-check matrices with identical stopping set distributions. Therefore, the MBBP decoder does not have to store all redundant bases, but rather a set of permutations, along with a low number of cog vectors that are known to have good stopping set properties. Note that this is a desirable property for practical applications: in order to generate a set of matrices with almost identical and good decoding performance, one only needs to determine the stopping set properties of the cog families rather than that of all individual cogs.

Let $\hat{f}$ denote the index of the optimal or near-optimal family. One vector $\text{cog}_{\hat{i}}, \hat{i} \in \mathcal{F}_{\hat{f}}$, and a subset of permutations in $\text{Aut}(\mathcal{C})$ suffice to generate a set of cogs from $\mathcal{F}_{\hat{f}}$. Depending on the set of available permutations, multiple cogs may be required to generate all cogs from the family $\mathcal{F}_{\hat{f}}$. With all these cogs at hand, one can construct the matrices $\mathbf{H}_\ell, \ell \in \mathcal{F}_{\hat{f}}$, required for MBBP decoding, by cyclically shifting the corresponding cogs, cf. Section 2.

For some classes of cyclic codes, stronger results are available on the structure of the automorphism group. For example, it is known that the automorphism group of a primitive BCH code contains the affine group - and BCH cog families are invariant under the action of every element of the affine group. On the other hand, the family of binary extended quadratic residue (QR) codes [26] with lengths $p+1$, where p is a prime, is known to have automorphism groups that contain permutations from the projective special linear group $PSL(p)$. For $p = 8m \pm 1$, the elements of this group can be written as

$$y \rightarrow \frac{ay + b}{cy + d}, \quad a, b, c, d \in \mathbb{F}_p, \quad ad - bc = 1.$$

A non-affine permutation in this group transforms cogs from one family into cogs that belong to a *different* family. As a result, the image of the original cog generates a parity-check matrix with different stopping set properties compared to the one generated by the original cog.

4 MBBP decoding

We describe next in more detail the operating principles of the MBBP decoders, and modifications thereof - as depicted in Figure 1 and 2, respectively. The basic components of an MBBP decoder are collections of (possibly redundant) parity-check matrices, and logical units that combine and process outputs of BP decoders operating on the matrices of the collection. We distinguish two basic MBBP architectures: one, which allows information exchange between decoders (*MBBP-X*) and another, where the decoder outputs are obtained without exchange of information (*MBBP-NX*). The decoders in the former category have the feature that information on the reliability of the received symbols can be exchanged *during* the process of iterative BP decoding; decoders in the latter class can only combine their results *upon termination* of their individual decoding processes. Both types of decoders can be implemented by storing a set of parity-check matrices. However, if only matrices based on one family of cogs are used, one needs to store only a low number of cogs, along with a set of permutations from $\mathcal{P}$.

The simplest architecture of an MBBP decoder is depicted in Figure 1, where the outputs of individual decoders are jointly processed only at the end of the decoding cycle. We refer to this technique as *standard* MBBP decoding (henceforth, MBBP-NX-S decoding).

4.1 MBBP-NX decoding

Standard MBBP decoding and its variation *First-success MBBP decoding* (MBBP-NX-FS) generate a collection of decoded words and then perform an additional metric selection within this set of words. The result of this processing is passed on to the *information sink*, which represents the gateway for the final codeword estimate of the decoder.

4.1.1 Standard MBBP decoding (MBBP-NX-S)

The MBBP-NX-S decoder runs multiple BP decoders in parallel, each of them separately and on a different parity-check matrix representation of the code. Let the parity-check matrix representation used by the ℓ -th decoder be denoted by $\mathbf{H}_\ell$, $\ell = 1, \dots, l$, and its decoded vector after at most N iterations by $\hat{\mathbf{c}}_\ell$, $\ell = 1, \dots, l$. We let $\mathcal{V} \subseteq \{1, \dots, l\}$ be the set of indices ℓ describing decoders that converged to a valid codeword. If none of the decoders converged to a valid codeword, we let $\mathcal{V} = \{1, \dots, l\}$. The words estimated by the decoders, $\hat{\mathbf{c}}_v$, $v \in \mathcal{V}$ are passed on to a *least metric selector* (LMS) unit, which determines the “best” codeword estimate using the decision rule $\hat{\mathbf{c}} = \underset{v \in \mathcal{V}}{\operatorname{argmax}} \Pr \{ \mathbf{Y} = \mathbf{y} \mid \mathbf{C} = \hat{\mathbf{c}}_v \}$. It is well known

that for the AWGN channel, this equation can be rewritten [22] as $\hat{\mathbf{c}} = \underset{v \in \mathcal{V}}{\operatorname{argmin}} \sum_{\nu=0}^{n-1} |y_\nu - \operatorname{map}(\hat{c}_{v,\nu})|^2$.

In this context, $\operatorname{map}(\cdot)$ defines the mapping of binary input symbols into antipodal signals (i.e. the BPSK modulation performed by the transmitter). The estimated information vector $\hat{\mathbf{u}}$ is obtained from $\hat{\mathbf{c}}$ in the standard manner. We choose a generator matrix of systematic form what provides several advantages, described in more detail in a companion paper [27]. Figure 1 depicts the operation of the

MBBP-NX-S decoder.

Figure 1: MBBP-NX-S decoding

4.1.2 First-success MBBP decoding (MBBP-NX-FS)

This type of MBBP decoder follows the standard approach in so far that it runs multiple BP decoders separately, each on a different parity-check matrix of the code. Denote the number of iterations required by the ℓ -th decoder to converge by N_ℓ . As soon as the first decoder, indexed by ℓ^* , identifies a codeword, the decoding process terminates. The estimate obtained by the decoder indexed by ℓ^* is passed on to the information sink. In the unlikely event that two or more decoders converge to a codeword after the same number of iterations, one of the outputs is randomly chosen from $\mathbf{c}_v$, where $v \in \mathcal{V}$ and where $\mathcal{V}$ is defined as for the MBBP-NX-S decoder. This approach requires only $N_{\ell^*} = \min_\ell N_\ell$ iterations to converge, and has therefore a significantly lower time-complexity when compared to MBBP-NX-S. When considering the average number of iterations to decode one codeword, this effect shows in particular in the low signal-to-noise ratio (SNR) regime.

The steps of these algorithms are summarized in Algorithm 1. Note that the tags of a selected set of steps and commands in the table indicate the algorithm during which these steps are executed. All untagged steps are executed both during the MBBP-NX-S and the MBBP-NX-FS procedure.

Line 2, 5, and 6 in Algorithm 1 describe the actions of detecting the first convergent decoder and terminating the decoding process. Although it can be easily shown that the MBBP-NX-FS algorithm cannot outperform its MBBP-NX-S counterpart, it provides for significant time savings, which makes it amenable for use in low-delay communication systems.

4.2 MBBP-X decoding

In this section we present MBBP approaches which allow for *periodic exchange* of information between decoders *during* iterative BP decoding. To this end, each decoder performs independently a given number of iterations, N_p , and afterwards exchanges information with other decoders only at iterations indexed by $\iota \cdot N_p$, where $\iota \in \mathbb{N}$. The *intrinsic information* of a given variable node depends only on

Algorithm 1 MBBP-NX: Standard (NX-S), and First-Success (NX-FS)

the channel output and is therefore equal for all decoders. For this reason, the decoders exchange only *extrinsic information* about the variable nodes. Figure 2 depicts the basic architecture of an MBBP-X decoder. As before, $\hat{\mathbf{u}}$ can be obtained from $\hat{\mathbf{c}}$ in a straightforward manner.

To emphasize that the messages exchanged between decoders represent extrinsic information, they are denoted by $\text{Pr}^{(e)}(\cdot)$. As part of their *cooperation scheme*, the decoders agree on the (extrinsic) probability values for each variable node. Afterwards, each decoder replaces its own information about a given variable node with the jointly derived estimate of the decoders, then calculates the *a-posteriori information*, and resumes decoding. For the purpose of computing the cooperative extrinsic probability, only a subset of active decoders $\mathcal{A}_\nu, \nu = 0, \dots, n-1$, is used. This subset is selected in terms of a *soft-metric* majority vote, which is described in more detail below.

4.2.1 Probability-Averaging MBBP (MBBP-X-PA)

This MBBP variation consists of the same basic steps as the standard MBBP algorithm, except for a periodic intra-decoder probability averaging feature. Probabilistic averaging was first described by the authors in [14], in the context of standard BP decoding. There, it was shown that it can lead to significant reductions in the error-floor of the performance curve. Here, averaging is used in a different context: periodically, the parallel decoders update their extrinsic probabilities by setting them to the average probability of a subset of the best performing decoders.

For this purpose, a soft-metric, weighted majority-vote $\bar{v}_\nu$ is calculated for a variable node ν according to

Figure 2: MBBP-X decoder architecture. The bus is active only if $i = \iota \cdot N_p$, $\iota \in \mathbb{N}$.

$$\bar{v}_\nu = \sum_{\ell=1}^l \log \left(\frac{\Pr^{(e)}(c_{\ell,\nu} = 0 \mid \mathbf{H}_\ell, \mathbf{y})}{\Pr^{(e)}(c_{\ell,\nu} = 1 \mid \mathbf{H}_\ell, \mathbf{y})} \right), \nu = 0, \dots, n-1. \quad (3)$$

The subset of decoders used in the described averaging process is defined as

$$\mathcal{A}_\nu = \left\{ \ell \mid \text{sgn}(\bar{v}_\nu) = \text{sgn} \left(\log \left(\frac{\Pr^{(e)}(c_{\ell,\nu} = 0 \mid \mathbf{H}_\ell, \mathbf{y})}{\Pr^{(e)}(c_{\ell,\nu} = 1 \mid \mathbf{H}_\ell, \mathbf{y})} \right) \right) \right\}, \nu = 0, \dots, n-1, \quad (4)$$

where $\text{sgn}(\cdot)$ denotes the sign function.

The averaged probabilities are determined as

$$\Pr^{(e)}(c_\nu = 0) = \frac{1}{|\mathcal{A}_\nu|} \sum_{\ell' \in \mathcal{A}_\nu} \Pr^{(e)}(c_{\ell',\nu} = 0 \mid \mathbf{H}_{\ell'}, \mathbf{y}), \nu = 0, \dots, n-1, \quad (5)$$

and

$$\Pr^{(e)}(c_\nu = 1) = 1 - \Pr^{(e)}(c_\nu = 0), \nu = 0, \dots, n-1. \quad (6)$$

We point out that the performance of this decoding approach strongly depends on the specific implementation of the proposed steps, as already pointed out in [14].

4.2.2 Highest-Reliability MBBP (MBBP-X-HR)

This approach is a simple modification of the MBBP-X-PA technique, and it employs the weighted majority-vote introduced in Equation (3) to select the decoders used for computing the information update subsequently forwarded to all decoders.

In this approach, the MBBP decoding architecture selects for each variable node an information update which is the most reliable output among all decoders, i.e.

$$\Pr^{(e)}(c_\nu = 0) = \Pr^{(e)}(c_{\ell^*,\nu} = 0 \mid \mathbf{H}_{\ell^*}, \mathbf{y}) \quad (7)$$

with $\ell^* = \underset{\ell' \in \mathcal{A}_\nu}{\operatorname{argmax}} |\operatorname{Pr}^{(e)}(c_{\ell', \nu} = 0 \mid \mathbf{H}_{\ell'}, \mathbf{y}) - 0.5|$, $\nu = 0, \dots, n-1$, and with A_ν given according to Equation (4). Note that $\operatorname{Pr}^{(e)}(c_\nu = 1)$ is calculated according to Equation (6).

4.2.3 Information-Combining MBBP (MBBP-X-IC)

The optimal method for deciding on the value of a random variable when multiple *independent* noisy observations of a variable are given is *information combining* [15].

The extrinsic information provided by the parallel decoders depends on their underlying parity-check matrices and the received codeword $\mathbf{y}$, and is hence not independent. Nevertheless, without assuming any optimality properties, we propose an MBBP decoding architecture which exchanges joint information about the variable nodes and determines this value by information combining. Information combining is also performed separately for each variable node as part of standard BP, and again only the decoders which agree with the soft-metric majority-vote according to Equation (3) are considered. In other words, only representations that have an index that belongs to the set $\mathcal{A}_\nu$, defined as in Equation (4), are used in this approach.

The “combined” probability distribution of the binary variable X_ν is given by

$$\operatorname{Pr}^{(e)}(c_\nu = 0) = \frac{\prod_{\ell' \in \mathcal{A}_\nu} \operatorname{Pr}^{(e)}(c_{\ell', \nu} = 0 \mid \mathbf{H}_{\ell'}, \mathbf{y})}{\prod_{\ell' \in \mathcal{A}_\nu} \operatorname{Pr}^{(e)}(c_{\ell', \nu} = 0 \mid \mathbf{H}_{\ell'}, \mathbf{y}) + \prod_{\ell' \in \mathcal{A}_\nu} \operatorname{Pr}^{(e)}(c_{\ell', \nu} = 1 \mid \mathbf{H}_{\ell'}, \mathbf{y})}, \nu = 0, \dots, n-1. \quad (8)$$

Again, one can use Equation (6) to calculate $\operatorname{Pr}^{(e)}(c_\nu = 1)$.

A summary of the steps for the three algorithms from the class of MBBP-X decoders is given in Algorithm 2. As before, the untagged lines are executed in all three algorithms, while the tags of the lines specify if the step is to be used in the X-PA, X-IC, or X-HR variation of MBBP decoding.

5 Results

As already pointed out, parity-check matrices that offer good performance when used for decoding signals transmitted over the BEC may also be good candidates for BP decoding over the AWGN channel [28]. The same characteristic of parity-check matrices was observed through extensive computer simulations for the variants of MBBP decoders, used over the AWGN channel.

In this section, we present performance results for MBBP decoders. Whenever possible, we provide a comparison of the error rates of MBBP decoders with those of a full search algorithm (maximum-likelihood, ML, decoding). If performing full search is computationally infeasible, but results on the weight distribution $\{A_i\}, i = 0, 1, \dots, n$, of the underlying code are available, we plot the union bounds

```

for the BER and FER as given by the expressions below:

$$\text{BER} \leq \frac{1}{n} \sum_{i=d}^n A_i \cdot i \cdot Q \left(\sqrt{2 \frac{k}{n} i \frac{E_b}{N_0}} \right),$$

$$\text{FER} \leq \sum_{i=d}^n A_i \cdot Q \left(\sqrt{2 \frac{k}{n} i \frac{E_b}{N_0}} \right).$$

Here, it is tacitly assumed that the transmitted codeword is the all-zero word, and A_i is used to denote the number of codewords of weight i in the given code. Furthermore, we compare our results to the *Gallager bound* (random coding bound) [29]. This bound considers an *ensemble* of block codes with length n and rate R and provides a tight upper bound on the average FER, denoted by $\text{E}\{\text{FER}\}$. In this context, the expectation is taken over the ensemble of codes. According to [29], the upper bound reads

$$\mathbb{E}\{\text{FER}\} \leq \exp \left(-n \cdot \max_{0 \leq \rho \leq 1} \max_{\Pr(\mathbf{X})} (E_0(\rho, 10 \log_{10}(E_b/N_0), \Pr(\mathbf{X})) - \rho R) \right), \quad (9)$$

where ρ , $0 \leq \rho \leq 1$, is a design parameter and $\Pr(\mathbf{X})$ denotes the probability vector of the possible channel inputs. Let us specialize this bound for the AWGN channel, which has discrete inputs and an SNR-dependent transition density function $f_y(y | x_i)$. Here, x_i is chosen from a finite set of cardinality M_x and y is a continuous variable, and thus

$$E_0(\rho, 10 \log_{10}(E_b/N_0), \Pr(\mathbf{X})) = -\ln \left[\int_{-\infty}^{\infty} \left(\sum_{i=1}^{M_x} [f_y(y | x_i)]^{\frac{1}{1+\rho}} \Pr(x_i) \right)^{1+\rho} dy \right].$$

We illustrate our findings on four short-to-moderate length codes; these codes belong to the class of cyclic and extended cyclic codes, and they include the [24, 12, 8] extended Golay code, the [47, 24, 11] quadratic residue (QR) code, the [31, 16, 7]-BCH code, as well as the [127, 64, 21]-BCH code. The maximum number of iterations is set to $N = 100$ for all codes and decoding approaches considered. Furthermore, N_p is set to 10 whenever MBBP-X approaches are simulated.

Throughout the remainder of this section, l is used to denote the number of parallel BP decoders in the MBBP architecture. For comparison, simulation results for standard BP decoding are presented as well. Also shown are the performance results of a BP decoder using the union of all parity-check equations in $\mathbf{H}_\ell$, $\ell = 1, \dots, l$, simultaneously, for the case of the [31, 16, 7]-BCH code.

5.1 The [24, 12, 8] Extended Golay Code

For the purpose of MBBP decoding of the extended Golay code, we use the result of Sections 2 and 3, and identify three different cog families denoted by $\mathcal{F}_1$, $\mathcal{F}_2$, and $\mathcal{F}_3$. For this, and all subsequently considered codes, one can generate cogs of a family by repeated application of permutations of type P_2 , shown in Equation (2). As an example, we will describe the process of constructing the parity-check matrices for the extended Golay code in more detail.

Since the code is an extended cyclic code, we construct the parity-check matrices from each cog in terms of 23 shifts performed on positions 0 to 22 while keeping the last position fixed. For the 24-th row of the parity-check matrix, we use the all-one codeword: this codeword preserves the stopping set distribution of the 23×24 matrix, and is the only parity check of the [24, 12, 8] extended Golay code invariant under all affine permutations. It is worth pointing out that there are other choices for the 24-th parity-check equation that may lead to slightly better overall performance - we use this parity-check matrix for simplicity of analysis. As a performance criterion for the cog families, we use the number of stopping sets up to size $d = 8$ in the parity-check matrices $\mathbf{H}_\ell$, $\ell \in \{\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3\}$.

We consider one representative cog for each family, termed cog $\mathcal{F}_f$, $f = 1, 2, 3$. A list of these cogs is given below.

	$ \mathcal{S}_\sigma(\mathbf{H}_\ell) , \ell \in$		
	$\mathcal{F}_1$	$\mathcal{F}_2$	$\mathcal{F}_3$
$\sigma \leq 5$	0	0	0
$\sigma = 6$	0	437	46
$\sigma = 7$	1357	10143	1495
$\sigma = 8$	25783	73209	20631

Table 1: Number of stopping sets for the $[24, 12, 8]$ extended Golay code, with parity-check matrices $\mathbf{H}_\ell$, $\text{cog}_\ell \in \mathcal{F}_f$, $f = 1, \dots, 3$.

$$\begin{aligned}
\text{cog}_{\mathcal{F}_1} &= 110101001100100000001000 \\
\text{cog}_{\mathcal{F}_2} &= 111000001001100000100001 \\
\text{cog}_{\mathcal{F}_3} &= 110100110000000101001000
\end{aligned}$$

Each $\text{cog}_{\mathcal{F}_f}$, $f \in \{1, 2, 3\}$, allows for generating all cogs in the family $\mathcal{F}_f$ by repeated application of permutation P_2 to the first 23 positions of $\text{cog}_{\mathcal{F}_f}$ while keeping the last position fixed, cf. Equation (2). The permutation P_2 is an automorphism of an extended cyclic code and preserves the stopping set distribution of the matrices $\mathbf{H}_\ell$, $\ell \in \mathcal{F}_f$, cf. Claim 3.5. The number of stopping sets in $\mathbf{H}_\ell$, $\ell \in \{\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3\}$, is summarized in Table 1. Note that the matrices of the considered families differ significantly from the near-optimal and highly redundant matrices used for decoding over the BEC, given in [6] and [7]. Due to the high redundancy, these matrices are not amenable for decoding over the AWGN channel, where short cycles may significantly degrade the performance of iterative decoders.

The $[24, 12, 8]$ extended Golay code is self-dual and contains 759 codewords of minimum weight 8 which can be partitioned into 33 cyclic orbits. Again, these cyclic orbits can be partitioned into three families of equal size. In other words, each family $\mathcal{F}_f$, $f = 1, 2, 3$, contains 11 cogs.

If matrices from the same family are used for signaling over the BEC, they provide the same performance under iterative decoding. Interestingly, the simulation results presented below show that the same is true for decoders used over the AWGN channel.

Figure 3 shows the BER performance of MBBP-NX-S decoding and MBBP-NX-FS decoding as well as MBBP-X-PA, MBBP-X-HR, and MBBP-X-IC of the extended Golay code. For all decoder types, $l = 11$ parallel BP decoders are used, for which the parity-check matrices are all drawn from the same family. FER performance results show similar characteristics. These results are not plotted due to space limitations.

It can be observed for all approaches that MBBP decoders using matrices $\mathbf{H}_\ell$, $\ell \in \mathcal{F}_1$, have the best performance, followed by matrices $\mathbf{H}_\ell$, $\ell \in \mathcal{F}_3$. This finding is supported by the stopping set distribution of Table 1, showing that the first family contains matrices that do not have stopping sets of size up to six and a low number of stopping sets of size seven. Matrices from the other two families have stopping sets of size six and exceed the number of stopping sets of size seven of the first family.

Figure 3: Performance comparison for the $[24, 12, 8]$ extended Golay code using $\mathbf{H}_\ell$, $\ell \in \mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3$.

The performance of MBBP decoders using parity-check matrices $\mathbf{H}_\ell$, $\ell \in \mathcal{F}_2$, is significantly worse than that of the two other classes - matrices in this family have 437 stopping sets of size six and over 10,000 stopping sets of size seven.

The performance obtained by means of the MBBP-NX-S with $l = 11$ is approximately 0.75 dB better than standard BP and performs close to the ML decoding bound. When performing a direct comparison of MBBP-NX-S and MBBP-NX-FS decoders, cf. Figure 3, one can observe that MBBP-NX-FS follows the performance of MBBP-NX-S very closely. However, simulation results show a significant gap in the average number of iterations required for successful decoding when comparing these approaches. As the shapes of these curves show similar characteristics, and due to space limitations, these results are only plotted for the $[127, 64, 21]$ -BCH code. It was observed for all codes discussed within this paper that MBBP-NX-FS requires significantly fewer iterations per decoder than MBBP-NX-S and BP decoding.

It is worth pointing out that the MBBP-X-PA and MBBP-X-HR algorithms produce similar results for all possible choices of cog families. Also, if the cogs are chosen from $\mathcal{F}_1$ or $\mathcal{F}_3$, the MBBP-X approaches outperform standard BP decoding, but do not attain the performance of MBBP-NX decoders. If the decoders operate on parity-check matrices constructed from cogs in $\mathcal{F}_2$, very poor performance results and error floors are observed in most of the cases. MBBP-X-IC decoders perform very poorly, regardless of the family considered. A probable cause for this phenomena is the strong correlation of the data, which makes information combining techniques highly suboptimal.

5.2 $[31, 16, 7]$ -BCH code

The dual of the $[31, 16, 7]$ -BCH code, denoted by $\mathcal{B}_1^\perp$, has minimum Hamming distance equal to eight. The minimum-weight codewords in $\mathcal{B}_1^\perp$ can be partitioned into 15 cyclic orbits. The corresponding cogs belong to one single family - as a result, all cog-based parity-check matrices of cyclic form with the same

number of rows are expected to have comparable performance. In this special case we require 3 cogs, all from the same family, to generate the 15 possible cogs. A list of these cogs is given below.

$$\begin{aligned}\text{cog}_{\mathcal{F}_{1,1}} &= 1111000010011000000000000000 \\ \text{cog}_{\mathcal{F}_{1,2}} &= 1100001100000101000000000000 \\ \text{cog}_{\mathcal{F}_{1,3}} &= 111000000000100101000010010\end{aligned}$$

Figure 4 visualizes the performance results for MBBP decoding of the $[31, 16, 7]$ -BCH code. We used $l = 6$ decoders for the MBBP-NX, MBBP-X-PA, MBBP-X-HR, and MBBP-X-IC algorithms.

Figure 4: Performance comparison for the $[31, 16, 7]$ -BCH code.

It can be observed that the MBBP-X techniques and the MBBP-NX-FS decoders have inferior performance compared to the MBBP-NX-S approach. Yet, these approaches require fewer iterations when more decoders run in parallel, i.e. they usually operate with lower complexity. It is worth mentioning that the NX-FS approach exhibits better performance than standard BP decoding and requires fewer iterations for successful decoding.

The performance curve labeled “stacked” corresponds to a BP decoder operating on a parity-check matrix which contains the union of parity checks present in $\mathbf{H}_\ell$, $\ell = 1, \dots, 6$. Observe that this performance is significantly worse even when compared to a standard BP decoder running on $\mathbf{H}_\ell$, $\ell \in \{1, \dots, 6\}$. Reasons for this include the local cycle distribution of the stacked matrix. All matrices $\mathbf{H}_\ell$, $\ell = 1, \dots, 6$, have a large number of short cycles, and the stacked matrix has an even larger number of such cycles, and is therefore not a good candidate for BP decoding.

5.3 [47, 24, 11]-QR code

We present next MBBP simulation results for the [47, 24, 11]-QR code, henceforth denoted by $\mathcal{Q}$. The code $\mathcal{Q}^\perp$ has minimum Hamming distance 12, and there exist 276 codewords of this weight. These codewords can be partitioned into eight cog families, labeled $\mathcal{F}_1$ to $\mathcal{F}_8$. In order to identify the family with best stopping set properties, we compute the number of stopping sets of size up to and including $\sigma = 9$ in cog-based matrices of each family. Table 2 allows for identifying the family with the best stopping set properties, $\mathcal{F}_3$. This family contains 23 cogs. Figure 5 plots simulation results for $l = 23$ representations with cogs chosen from $\mathcal{F}_3$.

	$ \mathcal{S}_\sigma(\mathbf{H}_\ell) , \ell \in$							
	$\mathcal{F}_1$	$\mathcal{F}_2$	$\mathcal{F}_3$	$\mathcal{F}_4$	$\mathcal{F}_5$	$\mathcal{F}_6$	$\mathcal{F}_7$	$\mathcal{F}_8$
$\sigma \leq 7$	0	0	0	0	0	0	0	0
$\sigma = 8$	47	0	0	47	47	47	94	47
$\sigma = 9$	$\times$	2961	2209	$\times$	$\times$	$\times$	$\times$	$\times$

Table 2: Number of stopping sets for parity-check matrices of cyclic form for the [47, 24, 11]-QR code.

Figure 5: Performance comparison for the [47, 24, 11]-QR code.

We list the results for the [47, 24, 11]-QR code as these results allow to point out two remarkable properties of MBBP decoding. First, we observe that MBBP decoding can provide a decoding performance which is superior to the performance reported by the Gallager bound. This is remarkable, as the Gallager bound indicates desirable performance results for codes of given length and rate. Compared to this bound, standard BP decoding obtains by far poorer performance results. Second, the [47, 24, 11]-QR code shows that non-standard MBBP decoders can outperform their standard counterparts. The approaches MBBP-X-PA and MBBP-X-HR lead to performance results close to MBBP-NX-S, while the approach MBBP-X-PA even outperforms MBBP-NX-FS. As in the previous examples, the MBBP-X-IC

decoder suffers from the introduced dependencies that arise due to data exchange between the decoders via information combining. For this reason, the latter approach shows a slightly degraded performance, yet still significantly better than that of standard BP.

5.4 [127, 64, 21]-BCH code

The [127, 64, 21]-BCH code, denoted as $\mathcal{B}_2$, has dimension 64 and a co-dimension 63. It is prohibitively costly to decode this code by means of an ML decoder or a trellis decoder. Also, it is computationally infeasible to find all minimum weight codewords of the dual code. Instead, we apply the algorithms provided in [30] to identify a tight upper bound on the minimum distance of the dual code as well as a (most likely incomplete) set of codewords with weight equal to the estimated minimum distance of the dual code. We report that 22 is an upper bound on the minimum distance of $\mathcal{B}_2^\perp$, and that at least 21 cog families exist. As it is a very complex task to identify the number of stopping sets up to the size $d = 21$ in a code of length 127, we approximate the performance criterion by evaluating only the number of stopping sets up to $\sigma = 5$. This allows us to conclude that all families yield comparable decoding performance.

Figure 6 shows the BER performance for different variants of the MBBP approach, where $l = 10$ decoders were run in parallel. There exist similar observations for the FER, but these results are not shown due to space limitations. Also given is the number of iterations required for the convergence of different decoding approaches. In this context, we distinguish between the average number of iterations required and the maximum number of iterations required to decode one codeword. It is also worth pointing out that these results are representative for all codes discussed in this work.

Figure 6: Performance comparison and number of iterations for the [127, 64, 21]-BCH code.

We observe a behavior that is characteristic for MBBP-NX decoding in connection with codes of high dimension and co-dimension. A significant performance improvement compared to BP decoding

is obtained. However, there remains a gap to the Gallager bound. For this particular code, we observe that MBBP-NX-FS is a very promising approach. In this case, a significant decrease in the number of average iterations can be obtained by using the MBBP-NX-FS decoder, while keeping the decoding performance close to that of the MBBP-NX-S class. However, all MBBP-X approaches perform very poorly. Reasons for this phenomena include the fact that, due to communication between the decoders, the number of “virtual short cycles” may be increased.

The performance of the MBBP-NX-S decoder matches the performance obtained with the ordered statistics decoding [2] for first order processing. The approach in [2] requires for each codeword a sorting of the received vector according to the received symbol reliability. Furthermore, a Gauss-Jordan algorithm is applied on the correspondingly resorted generator matrix, and, in order to obtain a decoding performance comparable to MBBP-NX-S with $l = 10$, up to 64 pattern tests are performed. We emphasize that MBBP avoids the use of Gauss-Jordan’s algorithm, which is the computationally most costly component of the decoder in [2]. Raising the number of test patterns further, the decoder in [2] can outperform the MBBP-NX-S approach with $l = 10$ parallel decoders. Similar observations are made for the Chase Type-2 algorithm. While MBBP-NX-S outperforms Chase Type-2 decoders for codes of short length [31], Chase Type-2 is superior for longer codes such as the $[127, 64, 21]$ -BCH code [32]. This is strongly related to the number of test patterns, which reads $2^{\lfloor d/2 \rfloor} = 1024$ and hence significantly higher than the diversity order in any reasonable MBBP-NX-S setup.

6 Conclusions

We introduced a class of decoding algorithms that operate in parallel on a judiciously chosen family of parity-check matrices. We considered two variants of this class of techniques: one, in which the decoders are not allowed to exchange information during individual runs of the BP algorithm, and another, in which periodic information exchange is allowed. Algorithms in the first class were shown to offer significant performance improvements when compared to the standard BP technique. The approaches in the second class often compare favorably to standard BP, but do not match the performance of algorithms that do not make use of periodic information exchange. Possible reasons for this behavior include the fact that “cycles” are created during the process of information exchange. These cycles “in-between” the graphs of the representations negatively affect the performance of each decoder.

The presented approaches were shown to work for classical high-density codes and are applicable to cyclic and extended cyclic codes. It is possible to generalize the introduced methods to codes like the progressive edge-growth (PEG) [33] family. For this class of codes, significant gains in performance can be obtained [34].
